Comparison of self-reported measures of alcohol-related dependence among young Swiss men: a study protocol for a cross-sectional controlled sample

Katia Iglesias,1,2 Frank Sporkert,3 Jean-Bernard Daeppen,4 Gerhard Gmel,4,5,6 Stephanie Baggio7,8

ABSTRACT

Introduction Short screenings of alcohol-related dependence are needed for population-based assessments. A clinical interview constitutes a reliable diagnosis often seen as gold standard, but it is costly and time consuming and as such, not suitable for population-based assessments. Therefore, self-reported questionnaires are needed (eg, alcohol use disorder (AUD) as in the Diagnostic and Statistic Manual of Mental Disorders (DSM) 5), but their reliability is questionable. Recent studies called for more evidence-based measurements for population-based screening (eg, heavy alcohol use over time (HAU)). This study aims to test the reliability of different self-reported measures of alcohol use.

Methods and analysis Based on stratified random selection, 280 participants will be recruited from the French-speaking subgroup of the Swiss National Science Foundation-supported Cohort Study on Substance Use and Risk Factors (C-SURF). This cohort is a population-based sample of young Swiss men in their mid-20s (n=2668). The sample size calculation is based on a proportion non-inferiority test (alpha=5%, power=80%, margin of equivalence=10%, difference in sensitivity between self-reported AUD and HAU=5%, correlation between AUD and HAU=0.35, and drop-outs=15%). Assessment will include a clinical interview as the gold standard of alcohol-related dependence, self-reported alcohol measures (HAU, AUD and drinking patterns), biomarkers as gold standards of chronic excessive drinking, and health outcomes. To assess the validity of the self-reported alcohol measures, sensitivity analyses will be run. The associations between alcohol-related measures and health outcomes will be tested. A non-response analysis will be run using the previous waves of the C-SURF study using logistic regressions.

Ethics and dissemination The study protocol has been approved by the Human Research Ethics Committee of the Canton of Vaud, Switzerland (no. 2017–00776). The results will be submitted for publication in peer-reviewed journals and presented at national and international conferences.

BACKGROUND Substance-related dependence is a major health concern worldwide, with alcohol being described as the substance leading to the most disabling mental disorders.1 Defining and measuring substance-related dependence is difficult and has led to various changes according to social, economic and political reasons.2 Indeed, substance-related dependence went through several shifts in terminology, definition, and measurement over the last 50 years.2,3 These changes were designed to improve its measure and aimed to be scientifically valid, clinically useful and understandable by the general public.4 Generally speaking, there is an agreement to define substance-related dependence as a syndrome of physiological, behavioural and cognitive phenomena developed after repeated substance use.4,5 Therefore, ‘alcohol-related dependence’ can be defined as a syndrome of physiological, behavioural and cognitive phenomena developed after repeated alcohol use. We prefer this term instead of ‘alcohol dependence’, which would be misleading because alcohol dependence has been used to define a distinct disorder in, for example, in the Diagnostic and Statistic Manual of Mental Disorders (DSM) IV5 and International Classification of Diseases (ICD) 11 and no longer exists in the DSM-5, which

Strengths and limitations of this study

- Evaluation of self-reported outcomes compared with a clinical interview based on the DSM-5.
- Inclusion of a large number of outcomes: clinical interview, biological material, and self-reported measures.
- Nested project in a longitudinal study: longitudinal data available for the participants included in the sample, non-response analysis.
- Only men in their mid-20s.
- The available data to test reliability of the self-reported measures are separated by one year.
Measuring alcohol-related dependence: the gold standard

Assessing alcohol-related dependence requires a clinical interview conducted by an experienced clinician in direct exchange with a patient. Indeed, a clinical interview provides a reliable diagnosis and it is often seen as a gold standard. Without an extensive anamnesis, it is difficult to establish a reliable diagnosis because alcohol-related dependence is a syndrome with several physiological, behavioural, cognitive and psychological processes, and not just 'a tick box of symptoms'.

Beyond clinical interviews, biochemical investigations are also used to assess chronic excessive drinking without asking people about their alcohol use. Biomarkers do not allow direct testing of the concept of alcohol-related dependence. However, they may be useful to screen for chronic excessive drinking, which may be a strong indicator of alcohol-related dependence. Since they do not rely on self-reports nor judgements of a clinician, they are of great interest in alcohol research.

However, clinical diagnoses and biomarker analyses are costly and time consuming and therefore not suitable for general population assessments that are needed for public health planning and monitoring, such as establishing prevalence rates, treatment planning, policy-making, and early intervention. Therefore, short quantitative measures of alcohol-related dependence are needed.

Alcohol-related dependence self-reported measures

Several self-reported measures of alcohol-related dependence are already available. In the recent developments of the DSM-5, alcohol-related dependence is measured through eleven criteria designed to diagnose AUD. However, despite the fact that AUD is well defined and that its measure addresses previous issues related to the diagnosis of the DSM-IV, several studies reported difficulties related to alcohol-related dependence’s measurement using self-reported measures (eg, refs 12–14). For example, the self-reported questions based on the criteria of AUD may be misinterpreted by respondents. Previous studies highlighted misinterpretation of DSM diagnostic criteria, contamination by negative thinking patterns of depressive people, lack of specificity, low positive predictive values (meaning that those who screen positive do not have the disorder), and lack of convergence with clinical diagnoses. Young heavy drinkers are especially concerned. They are likely to misinterpret survey questions and to share a misperception of AUD symptoms, such as after-effects and acute intoxication. Therefore, they are likely to over-report physiological symptoms of withdrawal and tolerance. Moreover, it seems that self-reports are not always consistent with clinical diagnoses. However, misspecification of self-reported AUD is understudied.

As a consequence of these pitfalls, a recent study called for more evidence-based measures. Some previous studies proposed heavy use as a suitable criterion in future classifications of substance-related dependence. Rehm et al. suggested that alcohol use over time, and more specifically heavy alcohol use (HAU) over time, is responsible for the physiological changes, symptoms, social consequences and burden of disease associated with the current definition of alcohol-related dependence. They concluded that HAU should be a relevant indicator of alcohol-related dependence. Moreover, the use of HAU also may diminish stigmatisation associated with alcohol-related dependence since alcohol use over time is less stigmatised than AUD. However, there are at least two important issues. The first one is the lack of definition of HAU: how many drinks are needed to defined ‘heavy use’, and how many months are needed to define ‘over time’? Currently, some indicators of alcohol use over time are available; for example, two drinks per day maximum is defined as low-risk alcohol consumption. Second, some studies reported that HAU is not a sufficient indicator of addictive behaviour, but empirical studies investigating this question using reliable measures of alcohol-related dependence have not been conducted. This measure does not aim to replace clinical assessments, which are compulsory for diagnostic evaluation and treatment, but would be of great interest for general population screening purposes. Thus, there is still a lack of consensus on which measure should be used and of empirical studies designed to test its reliability.

An alternative operationalisation of alcohol-related dependence has recently been suggested by Martin et al. They proposed that substance use disorders should focus on what they called ‘core’ features (ie, primary symptoms indexing internal dysfunctions) and not on ‘ancillary’ features (ie, consequences). According to these authors, consequences should not be used to measure substance-related dependence because they are context dependent, manifoldly determined and not necessarily related to one substance but to multiple substances. It is well established that AUD is associated with several detrimental consequences as consequences are part of the DSM-5 definition. However, non-disordered AUD can also result in consequences. Therefore, Martin et al. suggested assessing alcohol-related dependence with primary symptoms and removing consequences from its measure in order to get a more reliable measure; for example, to decrease the number of false negatives. To our knowledge, no empirical study tested this proposition, and data are thus needed.

Aim of the study

Based on clinical interviews designed to diagnose alcohol-related dependence, the main aim of this study is to test the quality of self-reported AUD to assess alcohol-related dependence in the general population. Another aim of this study is to test whether self-reported HAU can be used instead of self-reported AUD as a measure of alcohol-related dependence in a general population-based sample. It will also test whether self-reported
AUD focusing on primary symptoms and excluding alcohol-related consequences is a better assessment of alcohol-related dependence than self-reported AUD in its traditional definition.

**METHODS/DESIGN**

**Study design**
The study is a single-centre, national, controlled study with a stratified random sample selection and a cross-sectional design.

**Setting**
The study will be conducted in the Lausanne University Hospital (CHUV) in the Alcohol Treatment Centre. This facility is an urban public hospital serving 770,000 people. It is one of the five teaching university hospitals located in Switzerland.

**Population and sample**

**Population**
Our study is a large nested project of the ongoing longitudinal Cohort Study on Substance Use and Risk Factors (C-SURF) study supported by the Swiss National Foundation (SNF grant 33CSC0_122679, 33CSC0_139467 and 33CS30_148493). The C-SURF study is representative of young men around 20 years old. Young men are the study focus because they are a high-risk population regarding alcohol use. In collaboration with the C-SURF study, participation in the present project will be proposed to all French-speaking participants who were recruited within the Lausanne army recruitment centre and who answer the second follow-up of C-SURF in the following six months with a valid email address (n=2668). French speakers are the targets of this study because C-SURF covered all French speakers, whereas the German-speaking part uses only a subgroup of all German-speaking Swiss men. To focus on French speakers also reduces costs by using only one language for clinical assessment and a narrower area from which people have to travel for the clinical interview. In addition, C-SURF collected extensive data, and therefore additional detailed information about participants for the present project will be available. C-SURF also provides an up-to-date address registry and a tracking team, which will be useful to keep drop-out rates low.

**Recruitment**
First, all French-speaking men involved in the C-SURF study on 25 September 2017 with a valid email address have been invited by email to complete a ten-question online version of the Alcohol Use Disorder Identification Test (AUDIT) (five min) and have been informed that they may be contacted for the whole study if they are selected within the following six months. A second email was sent two weeks later to the participants who did not answer the questionnaire.

Second, we will select participants using a random stratified sample selection. All the participants who complete the AUDIT and meet the inclusion criteria (see below) will be separated in two strata (AUDIT ≥13; AUDIT <13), called groups hereafter. A total of 173 participants will be selected in the first group and 107 in the second group, using randomised numbers with the software R.

Selected participants will be contacted by phone by the psychologists to invite them to participate in the clinical assessment. An appointment at the CHUV will be scheduled if a participant agrees to participate. The whole procedure of recruitment is presented in figure 1.

**Procedure**
During assessment in the CHUV, participants will complete a computer-assisted questionnaire. Then, they will participate in the structured interview with a psychologist. Biological samples will be collected afterwards. The visit will take 90 min on average. The participants will be blinded to the group to which they belong. The interviewers will also be blinded to the participants’ group. The participant will be given an oral feedback on their alcohol use after the interview and a written feedback at the end of the study.

**Inclusion/exclusion criteria**
This study is nested in the C-SURF study, of which the inclusion criteria were:

![Flow diagram and timetable for the selection of study participants.](http://bmjopen.bmj.com/)

**Figure 1** Flow diagram and timetable for the selection of study participants.
will also be associated with increased self-reported AUD. We also hypothesise that RSOD drink heavily are probably risky single-occasion drinkers. We hypothesise that for the same moderate level of alcohol use, risky single-occasion drinking (RSOD) will be associated with a higher level of alcohol-related dependence than non-risky single-occasion drinkers. We hypothesise that for the same moderate level of alcohol use, risky single-occasion drinking (RSOD) with a score of zero on the first three questions of the AUDIT questionnaire related to alcohol use during the previous twelve months.

Hypotheses and research questions

Primary outcomes

Hypothesis 1
Self-reported AUD is not a reliable measure of alcohol-related dependence.

Hypothesis 2
HAU is a reliable measure of alcohol-related dependence.

Secondary outcomes
We also aim to investigate important secondary questions related to AUD and drinking patterns, as follows.

Research question 1
This question is related to the pattern of alcohol use and its relationship with alcohol-related dependence. Risky single-occasion drinkers, drinkers who drink six or more drinks on a single occasion, are more likely to be classified with alcohol-related dependence than non-risky single-occasion drinkers. We hypothesise that for the same moderate level of alcohol use, risky single-occasion drinking (RSOD) with a score of zero on the first three questions of the AUDIT questionnaire related to alcohol use during the previous twelve months.

Research question 2
The second question deals with cut-offs for the biomarkers of chronic excessive drinking. More investigations are needed in order to propose relevant cut-offs for (ethyl glucuronide (EtG)) in hair and PEth (phosphatidylethanol (PEth)) in blood. Evidence is still needed to define unhealthy alcohol use for decision-making. We will test the diagnostic performance of EtG and PEth compared with the clinical interviews. We will also test whether EtG and PEth are potential measures of RSOD, which is a question that has not been yet at focus, even if RSOD is a common drinking pattern among young people.

Research question 3
Another transversal research question will be to investigate non-response bias. Non-response bias is a crucial issue in surveys focusing on substance use. Indeed, contrary to most of the studies in which information about non-respondents are generally unavailable, data about the population (ie, C-SURF participants) will be available (eg, self-reported alcohol use, AUD, alcohol-related consequences, non-alcohol-related consequences, and mental and physical health). Therefore, we will be able to estimate non-response bias and predictors of non-response among participants who will be contacted to participate in the present study.

Endpoint

Primary endpoints

1. Alcohol-related dependence: Alcohol-related dependence will be assessed using a clinical interview over a twelve-month period. This diagnosis, our gold standard, will be based on the Diagnostic Interview for Genetic Studies (DIGS). It enables a comprehensive assessment of alcohol-related dependence and generates reliable diagnoses. It allows for the assessment of a comprehensive psychiatric diagnosis of alcohol-related dependence based on DSM-5 criteria. Its semi-structured format ensures homogeneity across patients and interviewers. We will add three questions related to craving.

2. AUD: We will measure AUD as defined in the DSM-5, with eleven criteria. We will use the cut-offs recommended in the DSM-5 to define presence or absence of AUD (ie, two criteria out of eleven criteria), and also a continuous scale of criteria (from 0 to 11, with a sum score of the eleven criteria). Moreover, following Martin et al, a restricted definition of primary symptoms of AUD will be computed by summing the items related to internal dysfunction (six criteria). We will use a continuous scale of criteria, since no cut-off is available for this operationalisation.

3. Alcohol use over time: Alcohol use over time will be measured with an extended quantity–frequency (QF) questionnaire. The extended QF questionnaire captures the variability in drinking habits better than with other instruments, providing separate information on weekends and weekdays over a period of time (twelve months in our study). The measures are converted into a total number of drinks per week by multiplying average frequency of drinking and quantity of drinking. In order to define HAU, we will test different cut-offs (eg, the traditional cut-offs of two and four drinks on average per day and empirical cut-offs).

Open access

► All young Swiss men at the army recruitment centre of Lausanne.
► All French-speaking cantons of Switzerland are included.
Within the French-speaking participants of the C-SURF, participants of the present study will be eligible if:
► They have a valid email address.
► They completed the AUDIT.
► They are randomly selected for the study's participation.
The exclusion criteria of our study are the following:
► They do not provide an informed consent to participate in the study.
► They have a score of zero on the first three questions of the AUDIT questionnaire related to alcohol use during the previous twelve months.

Hypotheses and research questions

Primary outcomes

Hypothesis 1
Self-reported AUD is not a reliable measure of alcohol-related dependence.

Hypothesis 2
HAU is a reliable measure of alcohol-related dependence.

Secondary outcomes
We also aim to investigate important secondary questions related to AUD and drinking patterns, as follows.

Research question 1
This question is related to the pattern of alcohol use and its relationship with alcohol-related dependence. Risky single-occasion drinkers, drinkers who drink six or more drinks on a single occasion, are more likely to be classified with alcohol-related dependence than non-risky single-occasion drinkers. We hypothesise that for the same moderate level of alcohol use, risky single-occasion drinking (RSOD) will be associated with a higher level of alcohol-related dependence, since this drinking pattern has been described as harmful. For example, people who drink seven drinks on Friday and Saturday (total 14 drinks per week) will have a higher level of alcohol dependence than people who drink three drinks on four different days (total 14 drinks per week). This hypothesis applies for moderate drinking levels because those who drink heavily are probably risky single-occasion drinkers (eg, five drinks per day). We also hypothesise that RSOD will also be associated with increased self-reported AUD.

Research question 2
The second question deals with cut-offs for the biomarkers of chronic excessive drinking. More investigations are needed in order to propose relevant cut-offs for (ethyl glucuronide (EtG)) in hair and PEth (phosphatidylethanol (PEth)) in blood. Evidence is still needed to define unhealthy alcohol use for decision-making. We will test the diagnostic performance of EtG and PEth compared with the clinical interviews. We will also test whether EtG and PEth are potential measures of RSOD, which is a question that has not been yet at focus, even if RSOD is a common drinking pattern among young people.

Research question 3
Another transversal research question will be to investigate non-response bias. Non-response bias is a crucial issue in surveys focusing on substance use. Indeed, contrary to most of the studies in which information about non-respondents are generally unavailable, data about the population (ie, C-SURF participants) will be available (eg, self-reported alcohol use, AUD, alcohol-related consequences, non-alcohol-related consequences, and mental and physical health). Therefore, we will be able to estimate non-response bias and predictors of non-response among participants who will be contacted to participate in the present study.

Endpoint

Primary endpoints

1. Alcohol-related dependence: Alcohol-related dependence will be assessed using a clinical interview over a twelve-month period. This diagnosis, our gold standard, will be based on the Diagnostic Interview for Genetic Studies (DIGS). It enables a comprehensive assessment of alcohol-related dependence and generates reliable diagnoses. It allows for the assessment of a comprehensive psychiatric diagnosis of alcohol-related dependence based on DSM-5 criteria. Its semi-structured format ensures homogeneity across patients and interviewers. We will add three questions related to craving.

2. AUD: We will measure AUD as defined in the DSM-5, with eleven criteria. We will use the cut-offs recommended in the DSM-5 to define presence or absence of AUD (ie, two criteria out of eleven criteria), and also a continuous scale of criteria (from 0 to 11, with a sum score of the eleven criteria). Moreover, following Martin et al, a restricted definition of primary symptoms of AUD will be computed by summing the items related to internal dysfunction (six criteria). We will use a continuous scale of criteria, since no cut-off is available for this operationalisation.

3. Alcohol use over time: Alcohol use over time will be measured with an extended quantity–frequency (QF) questionnaire. The extended QF questionnaire captures the variability in drinking habits better than with other instruments, providing separate information on weekends and weekdays over a period of time (twelve months in our study). The measures are converted into a total number of drinks per week by multiplying average frequency of drinking and quantity of drinking. In order to define HAU, we will test different cut-offs (eg, the traditional cut-offs of two and four drinks on average per day and empirical cut-offs).
4. Number of drinks according to past-week diary: The number of drinks during the past week assessed for each day separately will be added to create a total number of drinks for the whole week. A short-term recall measure (seven-day diary) will ask for the number of drinks during the past week on each day separately. This measure allows testing whether participants drink every day and how many drinks per day they drink.

5. Retrospective alcohol use: We will also collect more information on alcohol use over time using retrospective questions for participants at ages 10–15, 20 and 25 using questions used in the European Investigation into Cancer and Nutrition study, which described the trends of self-reported past consumption of alcohol use. Retrospective alcohol use will be modified to create an average number of drinks per week at ages 10–15, 20 and 25. This measure will provide information on alcohol use over time.

6. Biomarkers of chronic excessive drinking: We will use the EtG in hair and the PEth in whole capillary blood. Two locks of hair (alternatively arm/chest hair) will be collected to assess EtG, and a capillary blood sample on a dried blood spot will be taken to measure PEth. Both biomarkers will be analysed by liquid chromatography coupled to tandem mass spectrometry using ISO-validated methods (ISO: International Organization for Standardization). EtG and PEth are two recent biomarkers that appear especially reliable, whereas traditional biomarkers (carbohydrate-deficient transferring and gamma-glutamyltransferase) lack sensitivity and/or specificity, especially among young people showing a typical RSOD behaviour on weekends or special occasions. Hair EtG is efficient to detect alcohol abuse and cut-offs have been proposed for at-risk drinkers (>20/50 g of ethanol/day) and heavy drinkers (>60 g of ethanol/day). Its sensitivity and specificity are very high (>95%). On the contrary, it is less reliable for low levels of alcohol use. By contrast, PEth is useful to detect low levels of alcohol use during the last 2–4 weeks. Indeed, PEth has demonstrated a very high specificity (theoretically 100%).

Secondary endpoints

1. RSOD: RSOD is often measured with an ordinal scale (eg, ‘no RSOD’, ‘less than monthly RSOD’, ‘monthly RSOD’, ‘weekly RSOD’ and ‘daily RSOD’) and with a cut-off of five or six drinks on a single occasion. The current study will propose more precise operationalisation of RSOD (eg, number of drinks per occasion, duration of each occasion and continuous scale for number of occasions).

2. Health issues and illnesses: The Short-Form Health Survey will be included with its two subscales: the mental component summary (mental and social health) and physical component summary (physical health).

3. Consequences: Sixteen consequences already used in C-SURF, which are not explicitly substance related, will be selected from standard instruments.

4. Quality of life (QOL): WHO Quality of Life Instrument-BREF has been validated widely, and it was found to be reliable and valid for use among patients with alcohol-related dependence. There are 26 questions rated on a five-point scale composed of two general question of QOL and four dimensions: physical health (seven items), psychological health (six items), social relationships (three items) and environment (eight items). Each question was rated in reference to the last two weeks. A percentage rating within each domain is computed with scores ranging from 0 (lowest QOL) to 100 (highest QOL).

5. Life satisfaction: The Satisfaction With Life Scale (SWLS) will be used to assess life satisfaction. A mean score of the five questions of the SWLS will be computed.

Other variables

For the selection of participants, we will use the AUDIT. The AUDIT is a ten-item screening measure for AUD developed by the WHO, which includes three questions on dependence, four questions on specific consequences of harmful alcohol use and three questions on hazardous alcohol use. It has been described as a reliable screening tool of AUD.

We will also assess demographic variables: age, educational status, and professional status.

Based on the C-SURF data (three waves already collected and available), we will match information on demographics, health, and substance use.

Ethical aspects and safety

Consent and risks

All procedures performed in studies involving human participants will be in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Declaration of Helsinki and its later amendments or comparable ethical standards. There is no expected adverse event or side effect for participants. Informed consent will be obtained from all individual participants included in the study.

Confidentiality of the data

Data generation, transmission, storage and analysis of health-related personal data and the storage of biological samples within this project will strictly follow the current Swiss legal requirements for data protection and will be performed according to the Human Research Ordinance (HRO) Art 5. Data protection and confidentiality will be guaranteed.

Patient and public involvement

Patients and public were not involved.

Statistical analysis
Sample size
There is no available information about the psychometric properties of the self-reported AUD nor of HAU. Therefore, it was not possible to estimate a precise sample size in a power calculation. To ensure that we have enough alcohol-related dependent participants to test the hypothesis of HAU being equivalent or better than self-reported AUD, we made several sample size calculations based on different scenarios of possible sensitivity of self-reported AUD (sensitivity between 0.2 and 0.8) using a proportion non-inferiority test with alpha=5%, a margin of equivalence of 10% and a difference in sensitivity between self-reported AUD and HAU of 5%. The worst scenario is for sensitivity around 50% and no correlation between self-reported AUD and HAU. In this worst scenario, for a power of 80%, 135 alcohol-related dependent participants are needed (as shown in figure 2). In a favourable scenario, with a power of 80% and a middle/large correlation (supported by the C-SURF data: r=0.50), a total of 67 participants with alcohol-related dependence are needed. We decided to choose a scenario between the worst and the most favourable with a correlation between self-reported AUD and HAU of 0.35, which is a moderate correlation between two related but different concepts. In this scenario, 86 participants with alcohol-related dependence are needed. Therefore, we will select at least 86 participants with alcohol-related dependence and 86 participants without alcohol-related dependence.

The AUDIT score will be used to select participants. Alcohol-related dependence is defined with a cut-off of 13 at AUDIT, with a sensitivity ranging between 0.78 and 0.90 and a specificity ranging between 0.87 and 0.92. The positive predictive values were estimated between 0.40 and 0.88. Thus, by randomly selecting 151 participants with AUDIT greater or equal to 13 and a positive predicted value of 0.64 (midpoint between 0.40 and 0.88), there is a 95% probability of selecting at least 86 participants who are true positive. The negative predictive values were estimated at 0.97. Therefore, we will select 93 participants with AUDIT lower than 13 in order to have a 95% probability of selecting at least 86 true negative non-alcohol-dependent participants. The psychologists will be blinded to the participants’ AUDIT scores. In order to avoid issues related to attrition, we added 15% of participants in each group, a total of 173 participants with AUDIT ≥13 and 107 participants with AUDIT <13 will be invited in each group (n=280).

Data analyses
Analyses 1 (primary outcomes): HAU and AUD as measures of alcohol-related dependence
Considering the clinical interviews as a gold standard of alcohol-related dependence, and biomarkers as a gold standard of alcohol-related dependence, the data will be analyzed using appropriate statistical tests.
standard of chronic excessive drinking, we will test the
diagnostic performance of self-reported AUD and HAU
measures to see whether they are suitable ways to assess
alcohol-related dependence. We will use effect sizes to
compare the correlations (R² to test common variance
between measures and clinical effect size), and we will use
Fisher’s R to Z transformations to compare whether the
correlations are significantly different from one another.
Then, we will use dichotomised variables and test sensi-
tivity, specificity, positive predicted value, and negative
predicted value using the receiver operating characteris-
tic (ROC) curves. To dichotomise alcohol use, different
theory-oriented cut-offs will be compared (four, two and
one drink(s) per day), and data-driven models will also be
tested using stratum-specific likelihood ratio analysis and
machine learning (random forests).

Analyses 2 (primary and secondary outcomes): associations with
health outcomes and alcohol-related variables
We will compare outcomes’ associations with the gold
standards and the different self-reported measures
(HAU, self-reported AUD and self-reported AUD without
consequences). Effect sizes will be compared in order to
know which measure is the best predictor of health and
psychosocial issues and which one most resembles the
associations with the gold standards.

Analyses 3 (secondary research question): association of RSOD
with alcohol-related dependence
Associations of RSOD with the gold standard of alcohol-re-
lated dependence will be performed, adjusting for alcohol
use (extended QF questionnaire) to assess its independent
effect, and including an interaction between alcohol
use and RSOD to investigate their combined effect.

Analyses 4 (secondary research question): cut-off for biomarkers
and associations with RSOD
The diagnostic performance of EtG and PEth will be
calculated for their optimal cut-off values selected with
the ROC curves. Comparisons with clinical interviews,
and HAU will be performed. We will also test whether
EtG and PEth are potential measures of RSOD, using
EtG and PEth cut-offs to predict RSOD using correlations
and ROC curves. Different cut-offs will be tested in these
analyses.

Analyses 5 (secondary research question): non-response bias
We will compare non-respondents to respondents using
the information available in the previous waves of the
C-SURF study using logistic regressions.

All analyses will use a two-sided α=0.05. Statistical soft-
ware will include SPSS V.24, Stata V.15 and R.

DISCUSSION
The main aim of this study is to test the quality of the
self-reported AUD (also focusing on primary symptoms
and excluding alcohol-related consequences) and of the
self-reported HAU as measures of alcohol-related
dependence as defined by the DSM-5 in a general popu-
lation. The psychometric properties of the self-reported
AUD and of the HAU will be tested against a clinical inter-
view designed to diagnose alcohol-related dependence.

From an international perspective, the proposed project
aims to address some methodological issues highlighted
in recent studies related to the measure of substance-re-
lated dependence, and more specifically, alcohol-related
dependence. The project will provide evidence
regarding two important issues. First, it will test whether
self-reported AUD, which is extensively used in alcohol
research, is a reliable way to assess alcohol-related depen-
dence. Second, it will investigate whether HAU is a reli-
able measure of alcohol-related dependence. Therefore,
the study will provide insights on its capacity to capture
alcohol-related dependence. The results of the study may
have a large impact on future research on alcohol. It will
suggest a better way to assess alcohol-related dependence
in population-based samples and for screening perspec-
tives. Additionally, the project will investigate thresholds
needed for decision-making (early intervention and
treatment), test the effect of drinking patterns on self-re-
ported AUD, and determine cut-offs for biomarkers.
These cut-offs will be useful for legal medicine, which
needs further studies for decision-making regarding
alcohol abstinence.

From a national perspective, this study will provide a
valid prevalence rate of alcohol-related dependence
among French-speaking young Swiss men in their mid-20s.
It will be useful from a public health point of view. More-
over, cut-offs for unhealthy alcohol use will be proposed,
which may be relevant for preventive purposes and may
identify at-risk youths in Switzerland. It will improve
screening for unhealthy alcohol use. It would also be
useful for general practitioners to detect alcohol-related
dependent persons.35

The current study is designed to provide evidence
regarding the assessment of alcohol-related dependence
in the general population and especially among young
people. Potential benefits to society include a better
understanding and evaluation of alcohol-related depend-
dence, improvements of practices and future develop-
ment of adequate public health planning. It will help to
identify at-risk persons and groups. It may change the
practices from a clinical and public health perspective,
such as the use of alternative measures to screen for
alcohol-related dependence and identify at-risk alcohol
users, and from a research perspective, for example, to stop
using unreliable self-reported addiction scales and thus
to provide strong support to future findings in alcohol
research.
